Abstract: - Mobile computing is an empowering notion to many people. Different design and evaluation paradigms need to exist for mobile computing devices and environments. The context of use must be considered because there are multiple tasks taking place in many mobile computing interactions. However, few empirical studies on mobile computing regarding changes in context impact users’ abilities to perform effectively are conducted to date. This paper presents the detachment between the actual use and the evaluation of mobile devices by varying contextual conditions and recording changes in behavior. A study was conducted to examine the specific effects of changes in motion and lighting on user performance and workload. The results indicate that common contextual variations can lead to dramatic changes in behavior and that interactions between contextual factors are also important to consider.

Key-Words: - Mobile computing system, User’s contextual behavior, User’s performance, Mobile computing interaction

1 Introduction

Many real world mobile device interactions occur in context-rich environments. The value that can be added by enabling access to powerful electronic devices in a portable form has yet to be fully realized, but obviously has vast potential in terms of productivity and communication for business, personal, educational, and medical purposes, just to scratch the surface. However, there is currently a large gap between the vision of mobile computing that has been created and the existing state of mobile computing, due in part to the relative youth of the field, but also to the inherent challenge of designing devices that are intended to be mobile. In many mobile computing interactions, there are multiple tasks taking place, often with the mobile task being secondary, which is why the context of use must be considered.

In this investigation, context is presumed to be a set of conditions or user states that influence the ways in which a human interacts with a mobile computing device. This is consistent with other user-centered definitions of context, as described in Oulasvirta [1], Beale and Lonsdale [2], and Dourish [3], among others.

Even though user-centered context is understood to be important in the design and evaluation of mobile devices, and some appliance design approaches even acknowledge that contextual factors, such as ambience and attention, are crucial in device and task design, a surprising number of studies on mobile computing ignore the context of use relevant to the user. The need for understanding and learning from the design and real use studies is supported by Brewster [4], who, after experimenting with mobile device evaluation in a somewhat realistic situation, noted “a more realistic environment can significantly change the interaction and this must be taken into account when designing and testing mobile devices”. He further urges other researchers to employ more appropriate evaluation strategies, while Johnson [5] states a need for new evaluation methods that are specific to mobile computing and specifies the demands of evaluating mobile systems as one of his four problems of HCI for mobile systems.

A few recent studies have looked at the context of mobility explicitly, examining either how motion affects the evaluation of mobile computing devices [6,7] or how motion affects performance [8]. Additionally, Pascoe et al. [9] considered device requirements for mobile field workers.

The study described in this paper attempts to build upon this previous work as well as contribute a new level of rigor to the investigation of behavior in contextually rich environments, enabling deeper discovery of the specific effects of context on mobile device users. Ideally, this investigation will serve to show the benefits that can be obtained by investigating mobile devices in realistic contexts and convince other researchers to consider more realistic contexts during design and evaluation.

2 Methodology

2.1 Study objectives

In this study, three specific contextual factors (motion, and lighting level) were manipulated in order to determine their relative effects on performance of mobile device users. While there has been abundant discussion of strategies for adapting mobile devices to changes in context, the degree to which changes in context impact a user’s ability to perform effectively are relatively unknown. Therefore, a clearer understanding of the effects of some of these changes in context on the user can help designers of context-aware tools better focus their efforts, and prioritize their context-sensing projects. The contextual factors studied here are intended to be representative of a subset of particularly relevant aspects of context, but are by no means exhaustive. The goal is to establish a foundation by which the effects of context can begin to be more clearly understood.
2.2 Participants
One hundred and fifty participants were asked to perform a set of tasks on a mobile device while sitting, or free walking along a path around a room. Data from a subset of the participants, those who performed the tasks while sitting (“sitting group”) or while walking around the room (“walking group”), are examined in this paper.

The participants considered in the present study (N=90) volunteered over the course of one semester from Seoul high school. The participants were primarily juniors and seniors. The experimental tasks were performed on a cell phone called Samsung Anycall, however the tasks were designed such that prior experience with handheld devices was not required, as training was provided for each task and minimal input was needed to accomplish the goals of the tasks.

Each participant was randomly assigned to one of two groups: those who would be performing the tasks on a cell phone while sitting, and those who would be performing the same tasks on a cell phone while walking around a path with obstacles within an observation room. The two groups were found to be statistically similar in all demographic characteristics.

2.3 Experimental tasks and conditions
Each participant performed the task in each of the two lighting conditions. Participants in the sitting group performed the task while sitting at a table, while participants in the walking group performed the task while walking along a path that contained obstacles. There was one task used in this study: Reading Comprehension. These were each separate activities with separate goals and instructions.

2.3.1 Lighting level
The light level in the observation room was used as a within-subjects variable with two levels. The room that was used for both sitting and walking conditions contained nine sets of overhead fluorescent lights, each with three bulbs. In the High-Light condition all 30 bulbs were illuminated, resulting in an intensity of approximately 270 lux; in the Low-Light condition only the middle bulb for each of the nine sets of lights was turned on, reducing the lighting to an average of 90 lux. For all tasks, the cell phone backlight was turned off. The order in which each lighting condition occurred was randomized for each participant.

2.3.2 Task 1: Reading Comprehension
In order to assess a mobile device user’s ability to process information at a relatively deep level, a Reading Comprehension task was assigned to each participant. Given the widespread availability of eBooks [10] and other text document viewers for cell phones, reading comprehension was presumed to be of interest in the domain of mobile computing. The task involved reading paragraphs composed of fictional stories three to five sentences long and answering two multiple choice questions for each paragraph. The questions were taken from a book of standardized reading comprehension questions [11]. The tasks of reading and answering the multiple-choice questions were both carried out using a cell phone. A Samsung Anycall cell phone was used throughout the study for all participants. Participants read through five reading passages, each followed by two multiple choice questions in each of the two lighting conditions, for a total of ten passages of text and 20 questions. The same ten passages and 20 questions were used for all participants, but the order in which they were presented was randomized. Some scrolling was required for most of the reading passages and some of the multiple-choice questions, which could be done using either the up and down physical buttons on the device or by tapping small arrows on the screen with the stylus.

After participants finished reading a text passage they pressed a button at the bottom of the screen labeled “Done”, which took them to the first of two questions about the passage they had just read. Participants were not allowed to go back to the passage once they had pressed the “Done” button and were therefore instructed not to move onto the questions until they felt they had sufficient understanding of the content of the passages. Once on a question screen, participants would see the question followed by four radio buttons next to four answer choices. A “Submit” button was at the very bottom of the screen and was used to submit the participant’s choice once they had selected an answer from the list. On the first multiple choice screen the “Submit” button would take the participant to a screen with the next question and answer choices, which would then take the participant directly to the next passage of text to read or to a screen which read “Task Finished” if it was the last question in the task.

2.3.3 Condition 1: sitting
Participants assigned to the sitting group performed the task in both lighting conditions while sitting at a table in the observation room. They were provided with no specific instructions as to how to sit or whether or not to touch the table, only that they could not perform the task with the cell phone resting flat on the table.

2.3.4 Condition 2: walking
Participants assigned to the walking group performed the task while walking around a 1-ft wide path that had been taped to a carpeted floor. The path was a loop that wound around tables and chairs in the room, such that users could make multiple laps during a single task scenario. The initial direction that the participants walked along the path was randomly chosen, and then alternated for the remaining three task scenarios of the experiment. The room was approximately 35 ft wide by 35 ft long. Participants were instructed to keep both feet within the tape on either side of the path and informed that the number of times that they stepped on the tape would be recorded by the experimenter during the task. The number of full and partial laps that participants completed during the task scenario was also recorded by the experimenter, which was converted to distance (in feet) afterwards. There was no restriction on walking speed placed on the participants, only that they needed to keep moving.

2.4 Procedure
Before the experiment began, participants were given an introduction to the NASA-TLX workload assessment that was to be used in the study and given an opportunity to ask any questions about the meanings of the terms that were used. If the
participant had been assigned to the walking condition, the next step was to determine a representative walking speed of that participant by having them walk two laps (one lap in each direction) around the path in the observation room. This was done in order to familiarize the participant with the path, as well as to establish a baseline walking speed to assess how much of an effect performing the task on a cell phone had on their walking speed. Apart from this step, the procedures for participants in the sitting and walking groups were nearly identical.

Participants were given a verbal description of the task they would be performing on Reading Comprehension, accompanied by text instructions on the cell phone and then given a chance to perform practice trials. In the reading comprehension, this consisted of one passage of text, followed by one multiple-choice question. Practice trials were only given before the first scenario within the task. In the walking condition, participants performed the practice trials while walking around the taped path. Once participants verbally stated that they were comfortable with the task, the lighting level was adjusted to the scenarios at hand, and participants were instructed to begin the recorded trials.

Upon completion of the trials, participants filled out the NASA-TLX workload assessment. The lighting level was then adjusted to High-Light if the first scenario had been Low-Light or vice-versa. Participants then began the next set of trials for the same task. The NASA-TLX was then administered again, which completed the first task. Participants were then introduced to the next task and given practice trials before beginning. After the task had been completed, participants filled out a post-task questionnaire that asked them to indicate the degree to which the various factors in the study contributed to the difficulty of the task.

2.5 Hypotheses
Since very little previous empirical work has been done investigating the specific effects of task type, motion, and lighting, hypotheses were generated with a broad stroke, presuming that the contextual factors would affect the task and all experimental measures similarly. Casual observation dictated that the effects of motion would be greater than changes in lighting, in general. Therefore, the hypotheses for this study were as follows: 

Hypothesis 1 For the Reading Comprehension task, the effect of motion will yield strongly significant differences for all experimental measures.

Hypothesis 2 For the Reading Comprehension task, the effect of changes in lighting will yield significant differences for all experimental measures.

3. Results
In order to facilitate a more in-depth discussion, differences between conditions will be divided into three categories:

<table>
<thead>
<tr>
<th>Category</th>
<th>p value</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Not significant</td>
<td>p&gt;0.05</td>
<td>The conditions</td>
</tr>
</tbody>
</table>

3.1 Task 1: Reading Comprehension
A repeated-measures analysis of covariance (ANCOVA) statistical analysis was used to investigate differences between the independent variables. ANCOVA has the advantage that it is able to disentangle the effects of the independent variables (in this case lighting and motion) from the effects of covariates by including them in the regression model.

3.1.1 Motion
The mean adjusted values for the two between-subjects (motion) conditions as well as the results of statistical comparisons are listed in Table 1. TLX scores are unadjusted because they were not shown to be correlated with participant demographics. All times are in milliseconds.

<table>

</table>

An asterisk ("**") denotes significant.

These values are the raw means and have not been adjusted for the presence of covariates.

Table 3 F and p values for the motion × lighting interactions

In order to develop a more complete picture of the effects of the two conditions on performance, the graphs in Figs. 1,2,3,4, and 5 illustrate the change in performance as the independent variables were varied at each level. The four data points in each graph represent the adjusted values of the response variables for each of the four scenarios in the Reading Comprehension task.
4. Discussion and Conclusions

The results that were generated are rich with valuable information and have some degree of generalizability because the factors were carefully chosen to be representative of aspects of context encountered on a daily basis. Because context is so complex, it is important to have some degree of control when investigating its effects, therefore incremental advancements in the understanding of context may yield more benefit in the long term than attempts to quantify all effects at once.

Hypothesis 1: In the Reading Comprehension task, the effect of motion will yield strongly significant differences for all experimental measures. This hypothesis was partially confirmed. Score and TLX were shown to be strongly significant ($p=0.004$ and $0.001$, respectively) between motion conditions, while reading time was significant ($p=0.035$). Interestingly, response time and scrolls were clearly nonsignificant ($p=0.539$ and $0.585$, respectively). The lack of differences in response time could reveal that users were unable to process the text passages deeply, even though they took more time on them. This could indicate more difficulty in information encoding than information retrieving. Presumably, participants would have spent more time answering the questions in the walking condition than in the sitting condition if they felt that the necessary information was available to them, but was more difficult to access. It could be the case that, even though participants spent more time reading the passages and trying to encode them in the walking condition, the process of encoding was hindered by their motion. Thus, differences in the score measure between motion conditions were caused by inefficient processing of information during the reading phase. The lack of differences in the scrolls measure could indicate that participants were not less efficient in their reading strategy during the walking condition, because they did not use the scroll buttons more frequently.

Hypothesis 2: In the Reading Comprehension task, the effect of changes in lighting will yield significant differences for all experimental measures. This hypothesis was also partially confirmed. Similar to the results for the effect of motion, lighting yielded significant differences for some measures (response time, $p=0.050$; scrolls, $p=0.044$; TLX, $p=0.041$) and nonsignificant differences...
for others (reading time, \(p=0.309\), score, \(p=0.724\)). Interestingly, the measures that showed up as significant were, with the exception of TLX, the nonsignificant measures in the motion results. This indicates that changes in lighting affected users in a fundamentally different manner than changes in motion. Apparently, lighting affected users in a slightly more superficial way, leading to decreased reading efficiency (noted by more instances of scrolling) and response selection speed, but not accuracy. It is important to note that all noteworthy differences were significant and not highly significant, indicating that the changes in motion are able to influence user behavior in a more dramatic way than changes in lighting. Overall, the overarching hypothesis that the independent variables would influence all experimental measures similarly was generally not supported, as some measures, for the Reading Comprehension task, were very significant, while others were quite nonsignificant. This result is compelling, as it indicates that the way in which users’ behavior is affected by changes in context is not uniform. The other overarching hypothesis that users would be impacted similarly in the task was partially supported, as measures of time, score, and workload were significantly different between motion conditions. However, there were some discrepancies in the results for the lighting effects, as well as the degree of significance of the interactions. This is interesting because it indicates some effect of task type on user behavior even when the device and scenarios are the same. Additionally, the interactions between the contextual factors, which were not addressed in the initial hypotheses, presented some of the most interesting results. Workload interactions were nearing significance \((p=0.077\) and 0.065, respectively) for the Reading Comprehension task. When one considers the relatively controlled nature of this study, where most other contextual factors were held constant, the implications of this result for true real world conditions are enlightening. It should be a fairly safe assumption to conclude that the interaction effects would be even more dramatic when the number of variable contextual factors is increased, as in a typical real world mobile interaction scenario. This strongly indicates that mobile device evaluation in a static, seated, environment is likely to elicit far different behavior from users than they would exhibit in a real world situation. The results clearly indicate that common contextual variation has a clear, but diverse effect on the way in which users interact with a mobile device. Similar research looking at other contextual factors, or other levels of similar factors, would yield much needed empirically based insight into human behavior with mobile devices and allow context to be modeled and designed for much more appropriately. It is important that more research be conducted to investigate the ways in which changes in context impact user behavior because, as this study has shown, context does not affect people in a uniform way. Beyond that, people have a choice as to how they react in context-rich environments, and their behavior is often dictated by their own priorities as well as their abilities. The way in which users allocate available cognitive and physical resources when using mobile devices is very important. 

The results of this project indicate that context is a rich, nuanced, and variable condition. I believe that context is relevant and applicable in almost every situation and that investigations of context will be fruitful in any domain where a user has a specific goal that they are working toward, yet has multiple variables vying for their attention. These investigations should be catered to the domain being studied and should be designed to mirror realistic situations as closely as possible, while still retaining experimental control. Variable levels of noise may prove worthy of investigation, especially in the context of speech-based interactions. Extensive research has focused on improving speech recognition algorithms, making them more robust in the context of noise, and on developing hardware-based solutions such as noise canceling microphones. However, little has been reported with regard to user interactions with speech-based solutions under realistic conditions that include variable levels of noise. Ultimately, effective solutions to the challenges introduced by varying context will require a combination of hardware (e.g., noise canceling microphones), software (e.g., algorithms to stabilize stylus inputs when users are on the move), and careful design.
