#### Abstract

Homophonic cipher is developed as an alternative to substitution cipher to compose more resistant ciphertexts against to the frequency analysis attacks. Nevertheless, Attacking with taking advantage of characteristic vulnerabilities of the language is probable. In this paper, characteristic vulnerabilities of the Turkish Language for homophonic cipher are exposed and attacking approaches are illustrated.

Key-Words: Turkish n-gram Frequencies, Frequency Analysis Attacks, Homophonic Substitution, Monoalphabetic Substitution, Characteristic Vulnerabilities of the Turkish Language, Cryptoanalysis of Turkish Enciphered Texts.

## 1 Introduction

The idea of including homophony into cryptography thought as making stronger ciphers against frequency analysis attacks at the beginning. Homophonic cipher could be thought as extended version of substitution cipher. Homophonic cipher replaces each plaintext letter with different symbols proportional to its frequency rate. The frequency distribution of the ciphertext is manipulated and smoothed. Symbols located in ciphertext have relatively equal frequencies. Each symbol takes space of about one percent of ciphertext. That's why, it would be securer than a substitution cipher. Initially, ciphertext could be thought to resist any potential frequency analysis attack. However, homophonic enciphered texts still contain vulnerabilities and they are indirectly weak against to frequency analysis attack. Firstly, low frequent letters would repeat in a sufficiently long ciphertexts. Secondly, it would be taken advantage of the characteristic vulnerabilities of the source language.

At this point, Turkish is one of the least studied language. Related work by Dalkılıç [1] on the cryprographic patterns and frequencies in Turkish language investigates language patterns and frequencies of Turkish. That work could contribute solving homophonic ciphers but the study hasn't gone beyond the extraction of most frequent trigrams and contains limited information.

Moreover, tetragrams and pentagrams could play key role to solve homophonic enciphered texts but these information is almost unknown for Turkish. Above all, there are not previous studies on this subject for Turkish.

In this paper, firstly high frequent n-grams while n is less than, or equal to 5 are explored and secondly useful $n$-grams are illustrated to analysis of homophonic ciphers for Turkish. Data presented in this article collected from the data source size of 13.4 MB and the data source consists of 120 articles of a columnist, Çetin Altan, from the Turkish daily newspaper Milliyet and 37 novels of 9 different authors, which are Orhan Kemal, Orhan Pamuk, Çetin Altan, Aziz Nesin, Rıfat Ilgaz, Gülse Birsel, Ahmet Altan, Yılmaz Erdoğan and Soner Yalçın.

## 2 Cryptoanalysis of Homophonic Cipher

In order to solve homophonic ciphers, making a decision of useful n -grams belongs to source language plays pivotal role. The unigrams of $n$ grams should have low frequencies to be determined easily in homophonic encipherd texts, whereas the n -gram itself should have high frequency to be assumed to appear in the plaintext. In other words, high frequent n -grams should consist of low frequent unigrams.

For instance, most frequent trigrams are "lar"(\% 0,0078), "bir"(\% 0,0067) and "ler"(\% 0,006 ) in Turkish. However, "lar" would be expressed by $504(6 \times 12 \times 7)$ different symbols. Similarly, "bir" and "ler" would be shown by 189 and 378 symbols. Even if these trigrams are assumed to appear in ciphertext, it would almost be impossible to solve. That's why most frequent $n$ grams could not directly assist to solve homophonic ciphers. In contrast, the trigram of "gör" (\% 0,001) has high frequency, too. That's why, the trigram could be assumed to appear in the plaintext. Furthermore, it also would be expressed by 7 different symbols in Turkish homophonic enciphered texts. If the trigram had compared to most frequent trigrams specified above, it could have said that detecting the trigram would be much easier.

### 2.1 Unigram Frequencies

The unigram frequencies of the source language assesses how many symbols the letter would be expressed within homophonic cipher. Each letter would be replaced by different symbols proportional to its frequency rate.

Table 1. Turkish Unigram Frequencies and Replacing Values in Homophonic Cipher

| A \% 11,92 | 12 |  | \%5,114 | 5 |  | \%6,722 | 7 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

### 2.2 High Frequent n-grams Consisting of Low Frequent Unigrams

Firstly, we explore Turkish n-gram frequencies and obtain a table consists of $n$-gram and frequency columns for each n . Then, a virtual column named as "symbol", which indicates how many symbols the n -gram will be expressed within homophonic cipher by the use of unigram frequencies, was
created. Then, initial sorting was done with respect to the frequeny column by taking into account the first 250 records for bigrams, 1500 results for trigrams, 2500 results for tetragrams and pentagrams from the greatest to smallest. Thirdly, this new table was sorted with respect to the symbol column from the smallest to greatest. Finally, the values demonstrated in the tables obtained from this way. Since, it is needed to solve homophonic ciphers. Also, n -gram frequencies indicate frequencies in 11.371.564.

The bigram of "gö" consists of rare unigrams and it has a high frequency (The frequency of the most common bigram, "ar", is about \%0.02). If it is seen a bigram more than one times in ciphertext and its frequency would be about $\% 0.002(25203 / 11371564)$, it could be assumed to be "gö". The rest of the bigrams could
contribute to solve ciphertext but their frequencies are too close. It seems better to turn back after trying to detect more symbols via other $n$-grams.

Table 3 contains useful $n$-grams to solve ciphertext. Though the values are too close to each other, the trigram of "gör" and "uğu" could be evaluated as distinctive because of the frequency values.

Table 4 contains interesting values. The tetragram of "cumh" would be expressed by 12 different symbols. However, detecting the tetragram would be easy. The beginning and ending letter of the tetragram would be replaced with only 1 symbol and repeated everlastingly. Similarly, same rules are valid for tetragrams of "ptı $\breve{g}$ " and "vrup". Moreover, the tetragram of "çoси" and "görü" have a distinctive frequencies.

The challengest $n$-gram seems to be a member of pentagrams. The pentagram of "çocŭ̆" would be expressed by 6 different symbols. More interestingly, 3 letters of the tetragram, "ç,c, ${ }^{g}$ " would be repeated permanently in the ciphertext because each letter would be replaced with only 1 symbol. It would be easier to detect rest of the letters of the tetragram, " $o, u$ ", if the other letters are solved. Similarly, the pentagram of "foto $\breve{g}$ " is a interesting n-gram too. Whereas, first and last letter of the pentagram have about $\% 1$ frequency. Furthermore, the pentagrams of "çocuk" and "gördü" have a distinctive frequency. Another point that shouldn't be ignored is both the pentagrams of "çocŭ̆" and "çocuk" consisting of the distinctive tetragram of "çoси".

Distinctive n-grams exist as seen. It seems more meaningful to begin with looking for the bigram of "gö" first and attempting to solve pentagrams and tetragrams second. If it could be detected pentagrams or tetragrams in the ciphertext, it provides significant advantage in the rest of the process. Even if, these tetragrams and pentagrams don't appear in plaintext, distinctive bigrams and trigrams would most probably help to go ahead.

## 3 Conclusion

We have presented a novel method of exposing vulnerabilities of a historical encryption method for a specific language with taking advantage of its characteristic vulnerabilities.

Although the encryption method contains vulnerabilities for Turkish, it could clearly be said that the method is stronger than a classical substitution cipher. Moreover, it is needed to have a too long ciphertext to cryptoanalysis. If it is haven a long enough and uniform distributed ciphertext, distinctive n-grams would most probably contribute to detect vast majority of the letters of the alphabet. All in all, the method still maintains its resistance today against frequency analysis attacks if short ciphertexts have haven.
