New RBF neural network classifier with optimized hidden neurons number

Larbi Beheim, Adel Zitouni, Fabien Belloir Laboratoire d'Automatique et Microélectronique Université de Reims Champagne-Ardenne Campus du Moulin de la Housse, B.P. 1039, 51687 Reims Cedex 2 FRANCE

Abstract: - This article presents a noticeable performances improvement of a neural classifier based on an RBF network. Based on the Mahalanobis distance, this new classifier increases relatively the recognition rate while decreasing remarkably the number of hidden layer neurons. We obtain thus a new very general RBF classifier, very simple, not requiring any adjustment parameter, and presenting an excellent ratio performances/neurons number. A comparative study of its performances is presented and illustrated by examples on artificial and real databases.

Key-Words: - **RBF** neural networks, Mahalanobis distance, clustering, training algorithms, hidden neurons number optimization, burying tag identification.

1 Introduction

The radial basic functions neural net (RBF) has become, for these last years, a serious alternative to the traditional Multi-Layer Perceptron network (MLP) in the multidimensional problems. approximation RBF Network was employed since the Seventies under the name of potential functions and it is only later than [1] and [2] rediscovered this particular structure in the neuronal form. Since, this type of network profited from many theoretical studies such as [3], [4] and [5]. In pattern recognition, RBF network is very attractive because of its locality property which makes it possible to discriminate complex classes such as nonconvex ones. We consider in this article the Gaussian RBF classifier of which each m output s_i is evaluated according to the following formula:

$$s_{j}(X) = \sum_{l=1}^{N_{h}} w_{lj} \varphi_{l}(X) = \sum_{l=1}^{N_{h}} w_{lj} \exp\left\{-\frac{1}{2} (X - C_{l})^{T} \Sigma_{l}^{-1} (X - C_{l})\right\}$$
(1)

Where $X = [x_1 \dots x_n]^T \in \mathbb{R}^N$ is a prototype to be classified, N_h represents the total number of hidden neurons. Each one of these nonlinear neurons is characterized by a center $C_l \in \mathbb{R}^N$ and a covariance matrix Σ_L .

From a training set $S_{train} = \{X_p, \omega_p\}, p=1...N$ made up of prototypes couples X_p and its membership class $\omega_p \in \{1...,m\}$, the supervised training problem of RBF classifier amounts determining his structure, i.e. the number of hidden neurons N_h and the different parameters intervening in the equation of outputs (1). Whereas these parameters can be calculated by different heuristics, the estimate of N_h is often delicate. For that, many methods were developed among which we can quote [6], [7] and [8]. That they basic or are very sophisticated, these methods generally require a very significant load of calculation without however guaranteeing significant performances. Moreover, they often require a certain number of parameters that must be fixed a priori and optimized for a particular problem. So these methods cannot be applied systematically and without particular precautions to any type of classification problem. The article [9] proposed a very simple algorithm which generates automatically a powerful RBF network without any optimization nor introduction of parameters fixed a priori. Indeed, the algorithm automatically selects the number of the hidden layer neurons. Although this network is characterized by its great simplicity, it presents a major limitation however owing to the fact that it requires a rather significant number of neurons in the hidden layer. This limitation makes it very heavy and requiring very significant training times for the very large databases.

In this article we propose a solution to this problem by introducing the Mahalanobis distance. We thus obtain a new very general, very simple RBF network and presenting an excellent performances/neurons number ratio.

The organization of the article is as follows: In section 2, we describe the principle of construction of new RBF network and we present the associated algorithm. Its operation is illustrated for an example on an artificial database. In section 3, we study its performances, as well on artificial problems as real ones.

2 Algorithm

In this section, we describe the principle of construction proposed as well as the algorithm allowing its implementation. We illustrate then his operation in a problem of classification including two classes of which one is not convex.

2.1 Principle

The principle of the algorithm rests on [9]. According to the exponential nature of the functions $\varphi_l(.)$ of each hidden neuron, the activation state of each one of them decrease quickly when the vector of entry X moves away from the neuron center. So only an area of the entry space centered in C_l will provide a significantly non null activation state. Contrary to [9], our algorithm regards this area as a hyperellipsoide centered in C_{l} . Indeed, the use of the Mahalanobis distance makes it possible to take into account the statistical distribution of the prototypes around the centers C_l and thus a better representation of classes shape. Our algorithm proposes to divide a nonconvex class into a set of hyperellipsoides called clusters. Each cluster corresponds to a hidden neuron and it is characterized thus by a center placing it in the entry space, a matrix of covariance indicating the privileged directions and a width calculating the extension of the hyperellipsoide. In the continuation, we will not make any more the distinction between a neuron and a cluster.

2.2 Description

Before describing the algorithm of construction of the RBF classifier, we will introduce some notations used thereafter. At the k^{th} iteration, one defines $C^{(k)}_{ij}$ like the i^{th} center $(i=1...m^{(k)}_{j})$ characterizing the class Ω_{j} . With each center a matrix with covariance is associated $\Sigma^{(k)}_{ij}$ and a width $L^{(k)}_{ij}$. We note $H^{(k)}_{ij}$ the hyperellipsoide of center $C^{(k)}_{ij}$ such as:

$$H_{ij}^{(k)} = \left\{ X_p \in \Omega_j, \left(X_p - C_{ij} \right)^T \Sigma_{ij}^{(k)-1} \left(X_p - C_{ij} \right) < L_{ij} \right\}$$
(2)

Each class is characterized by the area $R^{(k)}_{\ ij}$ defined as the union of all the hyperellipsoides $H^{(k)}_{\ ij}$ ($i=1...m^{(k)}_{\ j}$). We will also use the distance $d(R^{(k)}_{\ j},X)$ between a point

We will also use the distance $d(R^{(k)}_{j},X)$ between a point $X \in \Omega_j$ and its associated area $R^{(k)}_{j}$. This one is defined as the Mahalanobis distance between X and the nearest center $C^{(k)}_{ij}$ of $R^{(k)}_{j}$:

$$d(R_{j}^{(k)}, X) = \min_{i=1...m_{j}^{(k)}} \left(X - C_{ij}^{(k)} \right)^{T} \sum_{ij}^{(k)^{-1}} \left(X - C_{ij}^{(k)} \right)$$
(3)

Step 0 (initialization): For k=0, one define *m* clusters whose centers correspond to the barycentres of different classes $\Omega_i (N_i$ is the element number of Ω_i):

$$m^{(0)}_{j} = let \ C^{(0)}_{1j} = \frac{1}{N_j} \sum_{X_p \in \Omega_j} X_p, j = l...m$$
 (4)

$$\sum_{lj}^{(0)} = \frac{1}{N_j - 1} \sum_{X_p \in \Omega_j} (X_p - C_{lj}^{(0)}) (X_p - C_{lj}^{(0)})^T, j = 1...m$$
(5)

Step 1 (adjustment of the widths): The width $L^{(k)}_{ij}$ relating to the center $C^{(k)}_{ij}$ is defined like the half Mahalanobis distance between this center and the nearest center of another class :

$$L_{ij}^{(k)} = \frac{1}{2} \min_{\substack{t \neq j, s = \dots, m_t^{(k)} \\ i = \dots, m_t^{(k)}, j = \dots, m}} \left(C_{ij}^{(k)} - C_{st}^{(k)} \right)^T \Sigma_{ij}^{(k-1)-1} \left(C_{ij}^{(k)} - C_{st}^{(k)} \right)$$
(6)

Step 2 (search for an orphan point): We seek a point $X_i \in S_{train}$ not belonging to its associated area $R^{(k)}_{\alpha i}$ and most distant from this one:

$$X_{i} = \arg \max_{X_{s} \in Srain} d\left(R_{\omega_{s}}^{(k)}, X_{s}\right)$$
(7)

If such a point does not exist, go to the step 5.

Step 3 (creation of a new center): Point X_i found at step 2 becomes a new center composing the class $\Omega_{\alpha i}$:

$$m_j^{(k)} = m_j^{(k)} + 1, \ C_{m_j^{(k)},j}^{(k)} = X_i$$
(8)

Step 4 (Reorganization of the centers): The K-means clustering algorithm [17] is applied to the points of S_{train} pertaining to the class $\Omega_{\alpha i}$ in order to distribute as well as possible the $m^{(k)}_{j}$ centers. Calculate the new covariance matrices:

$$\Sigma_{ij}^{(k)} = \frac{1}{Card(H_{ij}^{(k)}) - 1} \sum_{X_p \in H_{ij}^{(k)}} \left(X_p - C_{ij}^{(k)} \right) \left(X_p - C_{ij}^{(k)} \right)^T$$
(9)

Do k=k+1 and go to the step 1.

Step 5 (determination of the weights): The weights matrix W^* which minimizes an error function, here selected as the sum square errors of classification, is given by:

$$W^* = \left[H^T H \right]^{-1} H^T T \tag{10}$$

where H and T are the matrices respectively gathering the activation function stats and the target outputs. These last are fixed at 1 when they correspond to the class of the point and 0 elsewhere.

2.3 Discussion

The initialization of the algorithm (step 0) could have proceeded by the random placement of a number of given centers. This technique is very current in the definition of an RBF network. The fact of choosing the initial centers as barycentres of the points X_p makes it possible to avoid this unforeseeable character and provides moreover the number of these centers. Thus, the result of the algorithm depends only on the composition of the training data. In certain cases where the classes are nonconvex, it may be that the barycentre of a class is inside another class. This situation is not prejudicial for the algorithm since this center will be moved during following iterations. The covariance matrix corresponding to each center is obtained from the associated training data. We will further see that other definitions of this matrix can give different results. In step 1, $L^{(k)}_{ij}$ is defined relatively to the minimal distance between the center $C^{(k)}_{ij}$ and centers of another class. This means that a partial covering between the clusters of the same class is authorized. From a practical point of view, that makes it possible to optimize the space occupation of the attributes by the various zones of receptivity and thus to reduce the number of clusters necessary to compose each class. The elliptic volume covered by each cluster is maximum without encroaching on neighboring classes. In step 2, the fact of choosing the furthest point from the region $R^{(k)}_{i}$ makes it possible to improve the effectiveness of the algorithm of K-means clustering used at step 4. It should be noted that this one relates only to the centers constituting the same class since the other centers did not change a position. It guarantees moreover a fast development of this area. In the network training (step 5), the target outputs are fixed arbitrarily at 1 when they correspond to the class of the point and 0 elsewhere. The motivation of this practice is artificially to create a brutal fall of the membership degree at the geometrical border of the class.

After k iterations, all the points of S_{train} belong to a cluster, the algorithm generated m+k clusters defining as many subclasses. The RBF network thus built comprises then $N_h=m+k$ hidden neurons. We can note that the algorithm converges necessarily. Indeed, in the "worst case" where none the classes is separable, there will be creation of a cluster for each point of S_{train} .

2.4 Illustration of operation

We will illustrate the significant phases of the algorithm on a classification problem of two concentric classes from the databases of "ELENA" project [10] [11]. This base makes it possible to determine the capacity of a classifier to separate two classes not overlapping but of which one is included in the second.

Fig. 1a. Initialization of the algorithm.

Fig. 1b. 1st iteration of the algorithm.

Fig. 1c. 2nd iteration of the algorithm.

Fig. 1d. Result of classification of the algorithm.

The RBF network comprises 2 inputs and 2 outputs. The figure 1a shows the 2 initial centers $\{C_1, C_2\}$ obtained following step 0. We can see that the two centers are almost confused. Each cluster induced is delimited by an ellipse of the width calculated at step 1. Obviously, the cluster of center C_2 is not sufficient to entirely represent the class Ω_2 . This one thus will be subdivided in several subclasses. With the first iteration of the algorithm, the

point noted X_i on the figure 1b is the furthest from the center C_2 and is out of the corresponding cluster. The addition of a new center compared to this point led, after application of the K-means, to the new distribution $\{C_1, C_2, C_3\}$ illustrated by the figure 1b. The point X_j is now the furthest from the center C_3 on this figure. After application of the K-means on this new configuration one leads to the figure 1c. After 4 iterations, the 2 classes are discriminated perfectly and the neuronal classifier comprises a total of 5 neurons (see figure 1d). After having determined the number of centers necessary and their positions, the weights of the network are calculated according to equation of step 5.

The algorithm thus manages to separate the two classes with only 5 neurons against 108 neurons for the old algorithm using the Euclidean distance and with a slightly higher rate of recognition: 98% against 97.75% for the old RBF.

3 Results

The object of this section is to evaluate the performances of the RBF classifier built by the algorithm presented in section 2. For that, we applied the classifier to various problems of classification comprising a variable number of attributes and classes and bearing on synthetic data as well as resulting from the real world.

3.1 Benchmarks

The benchmarks carried out here are studied in detail in ELENA project [10]. For each problem of classification, we have the results concerning the RBF classifier generated by the algorithm proposed as well as the performances of certain classifiers studied in [11]. It is about the classifier of the "k-nearest neighbor" (kNN) [12] who gives the best approximation of the Bayes recognition error and the of the Multi-Layer Perceptrons classifier (MLP) very widespread in the pattern recognition per connexionnist model [13]. The Learning Vector Quantization classifier (LVQ) proposed by Kohonen is a simple adaptive method of vector quantization. For other types of neural classifiers, see [11] and the included references. The RBFE classifier acts of that proposed in [9] using the euclidean distance. For each classifier, we calculate the average error of recognition (in %) on the test set obtained on 5 different experiments with the method of the "hold out" for counting the classification errors. The experimental protocol, which respects that used in ELENA project, consists in learning the classifier on half of the data then testing its performances on the second half of the base.

The first database is created artificially to highlight certain properties or gaps of the tested classifiers. The objective of the "Clouds" problem is to study the influence of two interlaced classes with nonlinear borders. The three last databases result from real problems. The "Phoneme" problem relates to the speech recognition studied in European project "ROARS project SPIRIT" [14]. The principal difficulty of this problem is great dissymmetry in the number of authorities of each classes. We will not present the "Iris" data very known in the pattern recognition [15]. To finish, the data of the "Texture" file relates to the recognition of 11 natural micro-textures such as grass, sand, paper or certain textiles [16]. Various information concerning the statistics and the analysis in principal components of these various data files can be found in [10] and the references included.

The figure 2 presents results on these various problems. The performances of the RBF classifier are slightly lower than the other classifiers for this first problem. This is explained by the significant interlacing of the two classes. The algorithm generates a neurons number close to the points number of training data and the capacities of generalization on the test set are thus very bad.

The error rate of our classifier RBF is generally weakest for each of the last three problems. This is checked whatever the number of classes to be distinguished and the quantity of available data for the training.

Fig. 2. Classification results on four different bases.

3.2 Study according to the neurons number

The object of this study is to show excel it performances/nombre report/ratio of neurons which our new classifier has. Not having the number of neurons of network MLP, this study is limited to only networks RBF of the preceding section.

Table 1 presents a comparison between the old RBF and the new one. We can see on this table the "compact" quality of our new classifier who gives comparable error rates or even lower while minimizing the hidden neurons number Nh. So, training times are much less significant. For the "Textures" database for example, the error rate is divided by 4, while the number of neurons is divided by 39. It was necessary less than two minutes to training our classifier and more than one hour for the old one.

Times of training are given here for an execution of the algorithm under MATLAB on a PC AMD Athlon XP 1800+.

Database	Classifier	Error(%)	N _h	Learning time(s)
Clouds	Old classifier	13,60	162	60
	This classifier	13,25	72	30
Phoneme	Old classifier	10,90	227	100
	This classifier	10,43	59	24
Iris	Old classifier	2,90	24	0,5
	This classifier	1,94	3	0,1
Texture	Old classifier	1,73	858	3900
	This classifier	0,41	22	100

Table. 1. Comparison performances, neurons number

 and training times of the two RBF classifiers.

3.3 The choice of the covariance matrix

One of the limits of this classifier is the estimate of the covariance matrix. The larger the size of the clusters is and the better is the estimate of this matrix. So the calculation of this matrix can sometimes reduce the rates of recognition. To cure this problem, other calculations of this matrix can be proposed to take into account more prototypes during the estimate of this matrix. Table 2 gives examples of calculation, errors and the corresponding number of neurons. One can see on this table that a different choice of the covariance matrix that proposed in section 2 can increase or decrease the rate error but the number of hidden neurons can only increase. But this number remains always largely lower than the number of neurons proposed by the old RBF.

Covariance matrix		Error (%)	N _h		
Σ=cov(C)	(a)	0,14	247		
$\Sigma = cov(J_i)$	(b)	0,27	38		
$\Sigma = cov(JC_i)$	(C)	0,41	22		
Σ=cov(J)	(d)	0,32	283		

Table 2. Error rate of the base Textures according to the choice of the matrix of covariance: (a) covariance of the centers, (b) covariance of the data of each class (c) covariance of the data of each center (d) covariance of the total database.

3.4 Application in code identification

The goal of our application is to detect and identify reliably different buried metallic codes with a smart eddy current sensor. Based on the principle of the induction balance, our detector measures the magnetic fields modifications emitted by a coil. These modifications are due to the presence of the metal codes buried on the top of the drains. A code is built from a succession of different metal pieces separated by empty spaces. Thus the identification of the codes allows the identification and the localization of the pipes (like water, gas,...) [18]. Several material improvements were carried out on our detector [21], but the identification of the codes always poses problems because of the similarity between the codes, the non-linearity of the answer according to the depth and the choice of a suitable coding of the signals [22]. To solve these problems, various methods of classifications were proposed. The first methods was based one the fuzzy logic theory, the Kohonen SOM, and an RBF classifier. The methods based on the fuzzy logic theory are the well-known Fuzzy Pattern Matching (FPM) [19] and the distributed rules (DR.) [20] developed among others by Ishibuchi. Among all these methods it is the classifier RBFE (Euclidean RBF) who gives the best results. But, these results remain insufficient for the great depths. It is for that we developed this new classifier to try to decrease rate errors and neurons number for a future integration of the classifier on programmable microchips.

A comparison is made between these different methods and the new RBF classifier.

	This classifier	RBFE	SOM	FPM	DR
Error (%)	5.0	6.2	11.3	8.3	7.1
N_h	68	135	-	-	-

Table 3. Results of code misclassification for the 5 pattern recognition methods implemented.

For a burying depth up to 80 cm, we obtain the results given in the table 3. We can notice that the result of the new RBF classifier is better than the others, and always with less number of hidden neurones.

4 Conclusion

We proposed a noticeable performances improvement of a neural classifier based an RBF network. The new classifier is very general and simple. It generates automatically a powerful RBF network without any introduction of parameters fixed a priori.

The number of hidden neurons is very optimized what will allow its use for the very large databases. Indeed,

the new classifier obtains excellent recognition results for a variety of different databases.
