Abstract: In order to investigate the impacts of the integration of wind farms into utilities network, it is necessary to analyze the transient performances of wind turbine generation systems (WTGS) with the appropriate transient models. According to the grid code requirements for a wind turbine with doubly fed induction generator (DFIG), the assessments of the impact on the electrical transient performances were investigated for the doubly fed wind turbine with different representations of wind turbine drive-train dynamics models, different initial operational conditions and different active crowbar trip time. Firstly, the different mathematical models of the doubly fed wind turbine were presented, including the electromagnetic transient models of DFIG, a one-mass lumped model, a two-mass shaft flexible model of the wind turbine drive train system, and the power decoupling control strategies of the grid-side converter and the rotor-side converter of DFIG. Secondly, the transient performances of the presented doubly fed wind turbine under a grid fault were compared and evaluated with different equivalent models, parameters and initial operational conditions. And thirdly, the effects of the active crowbar on the transient performances of the doubly fed wind turbine were also investigated, with the possible reasonable trip time of crowbar. The investigation have shown that the transient performances are closely correlated with the wind turbine drive train models, initial operational conditions, key parameters of wind turbine, and trip time of the crowbar circuit.

Key-Words: Wind power, Doubly fed induction generator, Drive train, Transient performance, Crowbar.

1 Introduction

In recent years, MW-level wind turbines are becoming more and more attractive[1,2], as the size of wind turbine increases, the flexibility associated with the wind turbine drive train system also increases, and so also its influence on the electrical transient performance of the wind turbine. In addition, as the penetration of wind power into power system increases, more wind turbines are needed to be interconnected to the grid in order to make the grid more robust and efficient in case of grid faults. So therefore, increasing levels of the grid-connected wind turbine generation system (WTGS) in the modern power system is necessitating the need for accurate transient models and transient performances analysis of WTGS[3,4].

Doubly fed induction generators (DFIG) are popular configurations for large current WTGS. The stator of a DFIG is connected to the grid directly and provides for variable speed operation by using a partially rated converter on the rotor side, so it is a common choice due to its smaller converter capacity than other variable speed constant frequency generators by a number of manufacturers of large wind turbines. There are a few reports investigating the transient models and transient performances of doubly fed wind turbines [5]-[18], however, the transient models are mainly focused on different generator models. For example, an 8th-order generator model is derived in [5]. A 3rd-order, 5th-order and 8th-order models are compared in [6] for the transient performance studies, the results have shown that there may be a few discrepancy with different models. In addition, the drive train system of the wind turbine is usually used by a simple one-mass lumped model for its transient stability analysis; however, the shaft flexibility may become more and more obvious with the increase of the capacity of the wind turbine. In order to exactly analyze the transient performances of the doubly fed wind turbine, it may be needed to consider the flexible effect of the wind turbine drive-train shaft system.

In this paper, the assessments of the impact on the electrical transient performances were
investigated for the WTGS with different representations of wind turbine drive-train dynamics models, different initial operational conditions, different fault clearing time, and different trip time of the active crowbar circuit. A two-mass model taking the drive-train shaft flexibility into account in the structural dynamics was presented. In order to compare the transient performances of the WTGS under the grid fault, the transient responses of a 3MW doubly fed wind turbine were investigated under super- and sub-synchronous operation during grid different voltage dips. And then, the effects of the active crowbar on the transient performances of the doubly fed wind turbine were also analyzed, including the possible reasonable trip time of the active crowbar circuit. Furthermore, the influence of different parameters of the wind turbine on transient stability was also studied.

2 Dynamic Models of a Doubly Fed Wind Turbine

2.1 Models of Drive-train System

![Fig.1 Schematic diagram of a wind turbine drive train system](image)

(a) a two-mass equivalent model  
(b) a one-mass equivalent model

![Fig.2 Schematic diagrams of the one-mass and two-mass equivalent models of the WTGS](image)

Fig.1 illustrates the main rotor structural components of a wind turbine namely: blades, hub, low-speed shaft, gearbox, high-speed shafts and generator rotor [7,17]. Modeling of a wind turbine drive train system is a complex one. According to the blade element theory, modeling of blade and shafts needs complex and many computations [9]. Moreover, it also depends on the detailed and accurate information about the rotor geometry. For this reason, only the transient event of the wind generator system is considered, an equivalent lump mass modeling method of wind turbine system is normally used. In this method, the model of the drive-train system can be built to consist of two masses, i.e. wind turbine mass and generator mass. The two masses are connected to each other with a shaft that has a certain stiffness and damping constant value. Fig.2 (a) shows the schematic diagrams of a two-mass equivalent model of a wind turbine drive train system.

The dynamic equation of this model is given as:

\[
\begin{align*}
2H_m \frac{d\omega_g}{dt} & = T_w - K_s \theta - D_s(\omega_w - \omega_g) - D_m \omega_w \\
2H_m \frac{d\omega_w}{dt} & = K_s \theta - T_e + D_s(\omega_w - \omega_g) - D_m \omega_e \\
\frac{d\theta}{dt} & = \omega_w(\omega_w - \omega_g)
\end{align*}
\]  

(1)

Where \( H \) is the inertia time constant, \( T \) is torque and \( \omega \) is angular speed. Subscripts \( g \) and \( w \) indicate the generator and wind turbine quantities, respectively. The shaft stiffness and damping constant value are represented in \( K_s \) and \( D_s \). \( \omega_0 \) is the base value of angular speed. All the quantities are in per unit value.

In order to make a comparison of the transient performances of the WTGS with different equivalent models, the traditional one-mass shaft lumped model is also presented, which is shown in Fig. 2(b). The equation for this model is also given as:

\[
2H_m \frac{d\omega_M}{dt} = T_e - T_v - D_m \omega_M
\]  

(2)

Where \( H_M \) is the inertia time constant, \( D_M \) is the damping constant value of turbine. \( \omega_M \) is the angular speed of generator. In this model the angular speed of turbine is equal to the angular speed of generator.

2.2 Control Strategy of Grid-side Converter

A vector-control approach is used with a reference frame oriented along the grid voltage vector position, enabling independent control of the active and reactive power flow between the grid and the grid-side converter. In the PWM voltage source converter, the d-axis current can be used to regulate
the DC-link voltage, and the q-axis current can be used to regulate the reactive power, which can be seen in Fig.3.

![Fig.3 Schematic diagram of a grid-side converter connected to the grid/transfomer]

Fig.3 shows the schematic diagram of the grid-side PWM voltage source converter, where \( u_{gabc} \) are the three-phase grid voltages, \( u_{gabc} \) are the three-phase grid-side converter voltages, \( i_{ga}, i_{gb}, i_{gc} \) are the three-phase grid-side converter currents, \( R_g \) and \( L_g \) are the inductor resistance and inductance, \( i_{dgs}, i_{dcr} \) are the grid-side and rotor-side DC currents, \( C \) is the DC-link capacitor.

The voltage balance equation of the grid-side converter can be expressed as:

\[
\begin{bmatrix}
  u_{ga} \\
  u_{gb} \\
  u_{gc}
\end{bmatrix} = R_g \begin{bmatrix}
  i_{ga} \\
  i_{gb} \\
  i_{gc}
\end{bmatrix} + L_g \frac{d}{dt} \begin{bmatrix}
  i_{ga} \\
  i_{gb} \\
  i_{gc}
\end{bmatrix} + \begin{bmatrix}
  u_{gca} \\
  u_{gcb} \\
  u_{gcc}
\end{bmatrix}
\]

(3)

By using the abc-to-dq transformation matrix, the following equation can be given:

\[
\begin{align*}
  u_{gd} &= R_g i_{gd} + L_g \frac{d}{dt} i_{gd} - \omega L_g i_{gq} + u_{gd} \\
  u_{gq} &= R_g i_{gq} + L_g \frac{d}{dt} i_{gq} + \omega L_g i_{gd} + u_{gq}
\end{align*}
\]

where \( u_{gd}, u_{gq} \) are the grid voltages in \( d \)- and \( q \)-axis, \( u_{gca}, u_{gcb} \) are the grid-side converter voltages in \( d \)- and \( q \)-axis, \( i_{gd}, i_{gq} \) are the grid-side converter currents in \( d \)- and \( q \)-axis, \( \omega \) is the electrical angular velocity of the grid voltage.

Neglecting the switch losses of the converter, the following equations can be obtained [16,18],

\[
\begin{align*}
  u_{dc} i_{dgs} &= \frac{3}{2} u_{gd} i_{gd} \\
  u_{gd} &= \frac{m}{2} u_{dc} \\
  i_{dgs} &= \frac{3}{4} m i_{gd} \\
  C \frac{du_{dc}}{dt} &= i_{dc} - i_{dcr}
\end{align*}
\]

(5)

where \( m \) is the PWM modulation depth of the grid-side converter.

From the above equations, it can be seen that the currents \( i_{gd} \) and \( i_{gq} \) can be regulated by using \( u_{gca} \) and \( u_{gcb} \) respectively. The control scheme utilises current control loops by \( i_{gd} \) and \( i_{gq} \), the \( i_{gd} \) reference value can be derived from the DC-link voltage error. In addition, the \( i_{gq} \) reference determines the reactive power flow between the grid and the grid-side converter. Usually the \( i_{gq} \) reference value can be set to zero, which ensures zero reactive power exchange between the grid and the grid-side converter.

A vector-control scheme for the grid-side PWM voltage source converter is shown in Fig.4, where \( u_{gabc}^* \) represents the reference values of the three-phase grid-side converter voltages, \( u_{gabc}^* \) are the reference values of the grid-side converter voltages in \( d \)- and \( q \)-axis, \( i_{gd}^*, i_{gq}^* \) are the reference values of the grid-side converter currents in \( d \)- and \( q \)-axis.

![Fig. 4 Scheme of grid-side PWM converter control]

2.3 Control Strategy of Rotor-side Converter

In order to analyze the transient performances of a wind turbine generator, a mathematical model including electromagnetic transients both in the stator and the rotor circuits of DFIG is usually used. According to a standard per-unit notation in a reference frame rotating at synchronous speed and a motor convention, the transient models of a grid-connected DFIG can be represented by the detailed differential equations of the flux linkages [11,12]

\[
\begin{align*}
  u_{sd} &= R_s i_{sd} + \frac{d\psi_{sd}}{dt} - \omega \psi_{sq} \\
  u_{sq} &= R_s i_{sq} + \frac{d\psi_{sq}}{dt} + \omega \psi_{sd} \\
  u_{rd} &= R_s i_{rd} + \frac{d\psi_{rd}}{dt} - s \omega \psi_{rq} \\
  u_{rq} &= R_s i_{rq} + \frac{d\psi_{rq}}{dt} + s \omega \psi_{rd}
\end{align*}
\]

(6)

where \( \psi_a, \psi_d, \psi_q \) are the stator flux linkage, and \( \omega \) is the electrical angular velocity.
The equations of flux linkage can be given as:

\[
\begin{align*}
\psi_{sd} &= L_{sd}i_{sd} + L_{m}i_{rd} \\
\psi_{sq} &= L_{sq}i_{sq} + L_{m}i_{rq} \\
\psi_{rd} &= L_{rd}i_{rd} + L_{m}i_{rq} \\
\psi_{rq} &= L_{rq}i_{rq} + L_{m}i_{rd}
\end{align*}
\]

(7)

Where \(\omega_s\) is the synchronous speed; \(u, \psi, i, R, L\) are the voltage, flux linkage, current, resistance and inductance; \(L_m\) is the mutual inductance between rotor and stator; subscript \(s, r\) indicate the stator and rotor of electric machine, respectively; subscript \(d, q\) indicate the \(d, q\) components, respectively; \(s\) is slip ratio of DFIG.

The stator active and reactive power of a DFIG can be given as:

\[
\begin{align*}
P_s &= \frac{3}{2}(u_{sd}i_{sd} + u_{sq}i_{sq}) \\
Q_s &= \frac{3}{2}(u_{sq}i_{sd} - u_{sd}i_{sq})
\end{align*}
\]

(8)

In order to implement the active and reactive power decoupling control, the stator voltage can be oriented, that is \(u_{sd} = U_s, u_{sq} = 0\).

The stator active and reactive power can be further obtained as:

\[
\begin{align*}
P_s &= -\frac{3}{2}L_s U_{sd}i_{sd} \\
Q_s &= \frac{3}{2}\left(\frac{U_{sd}^2}{\omega_s L_s} + \frac{U_{sq}L_{rd}i_{rd}}{L_s}\right)
\end{align*}
\]

(9)

The electromagnetic torque of a DFIG can be also given as:

\[
T_e = -n_p L_m \tilde{\psi}_s \times \tilde{i}_r = -n_p L_m \tilde{\psi}_r i_{rd}
\]

(10)

Fig. 5 shows a vector-control scheme for the rotor-side PWM voltage source converter, where \(u_{abc}^*\) represents the reference values of the three-phase rotor voltages, \(u_{rd}^*, u_{rq}^*\) are the reference values of the rotor voltages in \(d\)-and \(q\)-axis, \(i_{rd}^*, i_{rq}^*\) are the reference values of the rotor currents in \(d\)-and \(q\)-axis. The stator active and reactive power can be controlled by regulating the \(d, q\)-axis components of the rotor current. The compensated voltage equations can be shown as [12]

\[
\begin{align*}
\Delta u_{rd} &= R_s i_{rd} - s\omega_L(L_{rd}i_{rq} + L_{m}i_{rd}) \\
\Delta u_{rq} &= R_s i_{rq} + s\omega_L(L_{rd}i_{rd} + L_{m}i_{rq})
\end{align*}
\]

(11)

3 Transient Simulation of Doubly Fed Wind Turbine with Different Models

Fig. 6 shows the schematic diagram of a doubly fed wind turbine connected to the grid. In the following simulation, the input mechanical torque from wind energy can be kept at constant value during a grid voltage drop, which means the pitch control system cannot be in action during the electrical transient. In addition, the rotor-side converter is assumed to ride through the fault current even though for a three-phase short-circuit fault at the stator terminals of DFIG. The main parameters of a 3MW doubly fed wind turbine system are shown in Table 1.

In order to show and compare the effects of the different drive-train models on the transient performances, the transient performances are simulated for the doubly fed wind turbine with different grid voltage drops and different initial generator speeds. The following cases are investigated for 40% and 80% grid voltage drops under a super-synchronous and sub-synchronous generator speed, respectively.

### 3.1 40% Voltage Dip under Super-synchronous Operation

In this case, the symmetrical three-phase stator voltage drops 40% at $t=0.05s$, and at $t=0.15s$ the voltage is restored to its pre-sag value. Before the grid fault occurs, the generator rotor speed is set to be 1.2 p.u..

Fig. 7 shows the transient behaviors under this case. As it can be seen from Fig. 7(a) that the active power has a larger oscillation during the post-fault with the two-mass model in comparison with one-mass model of the wind turbine drive train. The results have shown that the maximal active power reaches about 1.1p.u. using the two-mass model when the grid voltage fault is cleared, however, this value is only 0.85p.u. by using the one-mass model. In addition, the reactive power is rarely affected by using different drive train models. As it can be seen from Fig. 7(c) that the rotor speed of DFIG has a larger oscillation during the post-fault for the two-mass model in comparison with the one-mass model. The maximal angular speed can reach about 1.219p.u. considering a two-mass model when the grid voltage fault is cleared, however, this value is only 1.203p.u. with the one-mass model. Furthermore, it can be also seen that the torsional torque has a large oscillation by using a two-mass model.

**Fig. 6** Control diagram of a grid connected doubly fed wind turbine

**Fig. 7** Transient responses of 40% voltage drop under the super-synchronous operation

- (a) Active power of generator
- (b) Reactive power of generator
- (c) Angular speed of rotor
- (d) Torsional torque
3.2 40% Voltage Dip under Sub-synchronous Operation

In this case, the symmetrical three-phase stator voltage drops 40% at \( t=0.05 \text{s} \), and at \( t=0.15 \text{s} \) the voltage is restored to its pre-sag value. Before the grid fault occurs, the generator rotor speed is set to be 0.87 p.u..

As it can be seen from Fig.8(a) and Fig.8(b), the active power and reactive power are rarely affected by using different drive train models. In addition, as it can be also seen from Fig.8(c) and Fig.8(d), the angular speed of rotor and the torsional torque have a larger oscillation during the post-fault by using the two-mass model in comparison with a one-mass model. The results have shown the angular speed and the torsional torque keep oscillating until \( t=11 \text{s} \) by using the two-mass model when the grid voltage fault is cleared, however, at \( t=0.25 \text{s} \) the angular speed keeps its pre-sag value by using the one-mass model.

3.3 80% Voltage Dip under Super-synchronous Operation

In this case, the symmetrical three-phase stator voltage drops 80% at \( t=0.05 \text{s} \), and at \( t=0.15 \text{s} \) the voltage is restored to its pre-sag value. Before the grid fault occurs, the generator rotor speed is set to be 1.2 p.u..

Fig. 8 Transient responses of 40% voltage drop under the sub-synchronous operation

Fig. 8 Transient responses of 40% voltage drop under the sub-synchronous operation

(c) Angular speed of rotor

(d) Torsional torque
As it can be seen from Fig.9(a), the active power has a larger oscillation during the post-fault by using the two-mass model in comparison with a one-mass model. The results have shown that the maximal active power can reach about 1.1p.u. by using a two-mass model when the grid voltage fault is cleared, however, this value is only 0.85p.u. by using one-mass model. The second peak value of the active power is 0.915p.u. by using a two-mass model during the post-fault, however, this value is only 0.707p.u. for the case voltage drops 40% in Fig.7(a).

As it can be seen from Fig.9(c) that the maximal angular speed can reach about 1.24p.u. by using a two-mass model when the grid voltage fault is cleared, which is larger than the value of the case voltage drops 40%. In addition, at t=3.5s the rotor speed can not be kept steady. Furthermore, as it can be seen in Fig.9(d) that the maximal torsional torque is -0.2p.u., this value is -0.48p.u. for the case voltage drops 40% Fig.7(d).

Therefore, it can be seen from the above several comparisons that it is necessary to use a two-mass drive train model for correctly analyzing the transient performance of the doubly fed wind turbine. The level of grid voltage drop, and different initial rotor speed condition have an important impact on the transient performances of the doubly fed wind turbine, especially for the higher level of grid voltage drop and the super-synchronous speed condition.

4 Transient Responses of Doubly Fed Wind Turbine with Different Parameters

In order to further analyze the effects of the wind turbine drive train shaft flexibility on the transient performance of the doubly fed wind turbine, based on the presented two-mass model of the wind turbine drive train, the transient responses are investigated with different shaft flexibility and inertia constant of turbine and generator. In the following simulation, the grid fault condition is assumed to be the same as 3.3.

Case-I: Simulation on different shaft flexibilities

The objective of this case is to present the effect of the shaft stiffness on the transient performances of the doubly fed wind turbine. Simulation is performed by using 3 values of 10, 5 and 0.3 for shaft stiffness constant, respectively. The transient responses of the active power and the rotor speed with different shaft flexibilities are shown in Fig. 10.

As it can be seen that the transient behaviors are closely dependent on the shaft stiffness constant by using the two-mass model. The active power and the angular speed response occur much higher oscillation amplitude and lower oscillation frequency when the smaller $K_s$ value is used, it also need longer time to restore steady state after the grid fault is cleared. Thus, the results have shown that: as the stiffness constant decreases, the torsion frequency becomes lower and the shaft flexibility becomes larger, the influence of the shaft stiffness on transient performances of the doubly fed wind turbine becomes more and more obvious.

Case-II: Simulation on different inertia constants

The objective of this case is to present the effect of different inertia constants on the transient performances of the doubly fed wind turbine. Assumed the shaft stiffness is a constant, viz., $K_s$ =0.3, the flowing simulation is performed by using 4 values for total inertia constants and 3 different $H_w/H_g$ values of the WTGS, respectively. The responses of the rotor speed are shown as Fig.11(a)-(b).
As it can be seen that the transient performances are also closely correlated to the inertia constant of the wind turbine and the generator. Either $H_w$ or $H_g$ is increased by 50%, the oscillation amplitude of the rotor speed can be decreased, however, the oscillation amplitude can be more significantly decreased with the 50% increase of $H_g$ as compared with the 50% increase of $H_w$. When both the $H_w$ and $H_g$ are increased by 50%, the rotor speed oscillation can be reduced obviously. In addition, assumed the total inertia of the WTGS is a constant, viz., $(H_w+H_g)=4.54s$, it can be also seen that the transient performances are dependent on the inertia constant ratio of the wind turbine and the generator $H_w/H_g$, it can be concluded that with the increase of the inertia constant ratio, the oscillation amplitude of the rotor speed can be also increased obviously.

5 Transient Responses of Doubly fed Wind Turbine with an Active Crowbar

In order to show the effects of the active crowbar on the transient performances of the doubly fed wind turbine, the transient performances are investigated with different trip time of the active crowbar circuit. Fig. 12 shows a schematic of a crowbar protection with three-phase AC switch and bypass resistor.

Case-I: In this case, the transient responses of the doubly fed wind turbine under 80% voltage drop are simulated by using the presented two-mass model. Before the grid fault occurs, the generator rotor speed is set to be 1.2 p.u.. The symmetrical three-phase stator voltage drops 80% at $t=0.2s$, and at $t=0.35s$ the voltage is restored to its pre-sag value. The crowbar circuit switches in when the grid fault is occurred, and simultaneously the rotor-side converter is closed and the grid-side converter is also in operation. After the grid fault is cleared, the crowbar circuit switch out and the rotor-side converter restart to work. The transient
performances of the doubly fed wind turbine with the active crowbar are shown in Fig. 13.

![Fig. 13 Transient responses when the stator voltage drops 80% and the crowbar circuit trips at 0.35s](image1)

As it can be seen from Fig.13 that when the crowbar circuit is tripped at 0.35s, the rotor current is 3.7p.u. which exceeds the threshold value, and the rotor voltage also exceeds the threshold value after the grid fault is cleared. The maximum value of dc-link voltage is about 1.32p.u.

**Case-II:** In this case, the transient responses of the doubly fed wind turbine under 80% voltage drops are also simulated. But the active crowbar circuit trips at t=0.5s, that is to say, the crowbar circuit will continue to work for 0.15s after the grid fault is cleared. The transient performances of the doubly fed wind turbine with the active crowbar are shown in Fig. 14.

![Fig. 14 Transient responses when the stator voltage drops 80% and the crowbar circuit trips at 0.5s](image2)

As it can be seen from Fig.14 that when the crowbar circuit trips at 0.5s, the dc capacitor voltages, the rotor current do not exceed the threshold value. Furthermore, the results have shown that there is much smaller oscillation of the transient performances as compared with the case I. Thus, it is necessary to select the appropriate trip time of the crowbar circuit to reduce the oscillation and improve the transient stability of the doubly fed wind turbine.

6 Conclusions
In order to investigate the transient performances of a doubly fed wind turbine with the appropriate transient models, a one-mass lumped model and a two-mass shaft flexible model of the wind turbine drive train system are presented. Based on the control strategies of the grid-side converter and the rotor-side converter of DFIG, the transient behaviors are simulated and compared by using different drive train models, under the conditions of different voltage sags and different generator initial speed. The simulation results have shown the wind turbines system model incorporating a two-mass drive train shaft model is important to analyze exactly the transient performance of the doubly fed wind turbine, the level of grid voltage drop and different initial rotor speed condition have an important impact on the transient performances of the doubly fed wind turbine, especially for the higher level of grid voltage drop and the supersynchronous speed condition. In accordance to the two-mass model with the more flexibility of the drive train, with the decrease of the total inertia constant or with the increase of the inertia constant ratio, the transient performances may cause larger oscillation, and maybe result into the unstable
operation of WTGS. Furthermore, the trip time of the active crowbar circuit also has an important influence on the transient behaviors, after the grid fault is cleared, the crowbar circuit continues to work a long time, which can be helpful to improve the low voltage ride-through ability. The results of the investigation of the transient models and the transient performances of the doubly fed wind turbine will provide a good technical support to the transient impacts of the integration of wind farms into utilities network in the future.
