Abstract: - The combination of MIMO and OFDM becomes a key standardization work for the downlink channel in 3G Long-Term Evolution (3G-LTE). This paper studies one of the core techniques of 3G-LTE downlink: the coding and decoding schemes in a time-variable multipath environment. It discusses the MIMO schemes for 3G-LTE downlink, the STBC/SFBC, SFTC/STTC and Group layered SFC coding-decoding schemes. This paper also discusses channel estimation scheme based on pilot symbol assistance (PSA), including the pilot pattern and the channel tracking algorithms. The computation complexity, frequency efficiency, BER performance and the effects of channel estimation are analyzed under multi-path fading channel environments. Then we give computer simulation results for the coding-decoding schemes. We believe that results will provide beneficial information to design the 3G-LTE downlink channels.

Key-Words: 3G long-term Evolution(3G-LTE), MIMO-OFDM- STBC/SFBC, SFTC/STTC, Group layered SFC

1 Introduction
Multipath fading channel and spectrum efficiency are the two severe challenges for 3G Long-Term Evolution (3G-LTE).

3G-LTE Data transmission in downlink is based on OFDMA. OFDM has been widely studied and it appears as the preferred multiple access schemes for 3G-LTE downlink. OFDM converts the wideband frequency-selective fading channel into multiple flat fading one. It is a popular modulation choice for many applications for its intrinsic ability to handle the most common distortions encountered in a wireless environment, without requiring complex reception algorithms. For independent fading of the users who occupied by the different subcarriers, OFDMA exploits multiuser diversity to meet users QoS requirement. Many OFDM like schemes have been proposed for 3G-LTE, such as MC-WCDMA, MC-TD-SCDMA, OFDMA, SC-FDMA, etc.

Furthermore, MIMO (multiple-input–multiple-output) smart antenna systems have the ability to turn multipath propagation, traditionally a pitfall of wireless transmission, into a beneficial factor for wireless communications. MIMO improves spectral efficiency by exploiting the rich scattering of RF signals which is typical for indoor and urban environments. There are mainly two ways to handle the wideband MIMO: MIMO wideband equalization and combination of MIMO and OFDM. MIMO wideband equalization is quite complex to implement. MIMO combined with OFDM substantially reduces the complexity of spatial-temporal processing. Then, MIMO-OFDM is a more effective solution for 3G-LTE.

Data transmission is based on MIMO-OFDM has been widely studied. However, the situation in 3G-LTE downlink is less clear considering the tradeoff among coding-decoding, channel estimation, the tracking of time varying and performance. In this paper, we discussed the 3G-LTE physical layer in the downlink direction, including the STBC/SFBC, SFTC/STTC, Group layered SFC coding-decoding schemes and channel estimation based on pilot symbol assistance (PSA). Their basic performance and computation complexity in time varying channel are simulated and compared.

The rest of the paper is structured as follows. Section 2 gives a briefly description of the LTE downlink physical (PHY) layer with MIMO. The MIMO coding-decoding schemes, the PSA pilot pattern and channel tracking schemes are presented and analyzed in Section 3. In Section 4, simulation results are presented. Finally, Section 5 gathers the conclusions and future work.

2 3GPP-LTE Downlink Model
The MIMO-OFDM system model for Space Time/Space Frequency (ST/SF) Coding in 3G-LTE downlink is shown in Fig 1 and Fig 2.
Suppose that the system is equipped with $M_T$ transmitting (Tx) antennas and $M_R$ receiving (Rx) antennas. The output signal from IFFT can be described as $s_q[n,m]$ in time domain

$$s_q[n,m] = \frac{1}{N} \sum_{k=0}^{N-1} S_q[n,k] e^{j \frac{2 \pi k m}{N}}$$  \hspace{1cm} (1)$$

The signal with guard interval ($N_g$) is

$$\tilde{s}_q[n,\tilde{m}] = \begin{cases} s_q[n,\tilde{m}+N] & \tilde{m} = -N_g, \cdots, -1 \\ s_q[n,\tilde{m}] & \tilde{m} = 0 \cdots N-1 \end{cases}$$  \hspace{1cm} (2)$$

For the $n$th OFDM symbol, the channel response between the $q$th transmitter antenna and the $i$th receiver antenna can be described as

$$h_{i,q}[n] = [h_{i,q}[n,0], h_{i,q}[n,1], \cdots, h_{i,q}[n,L-1]]^T$$  \hspace{1cm} (3)$$

where $i = 1, 2, \cdots, M_R$, $q = 1, 2, \cdots, M_T$ and $L$ is the channel order.

The received signal after matched filtering and the guard symbol removed are
where $y_i[n,m]$ is the AWGN noise with zero mean and variance of $\sigma_y^2$.

When the guard interval exceeds the maximum time delay of the channel ($N_g > L$), the Inter-Symbol-Interference (ISI) can be neglected and the received signal in frequency domain can be described as

$$Y[n,k] = \sum_{i=0}^{N-1} y_i[n,m] e^{-j \frac{2\pi km}{N}}$$

$$= \sum_{q=1}^{M_t} \left( \sum_{i=0}^{L-1} h_{i,q}[n,l] e^{-j \frac{2\pi nl}{N}} \right) S_q[n,k] + V[n,k]$$

$$= \sum_{q=1}^{M_t} H_{i,q}[n,k] S_q[n,k] + V[n,k]$$

(i = 1, 2, ..., $M_R$, k = 0, 1, ..., $N-1$)

where

$$H_{i,q}[n,k] = \sum_{l=0}^{L-1} h_{i,q}[n,l] e^{-j \frac{2\pi kl}{N}}$$

Suppose input information vector is $S_I = [S_I[0], S_I[1], ..., S_I[Q-1]]$, and $N > M_T L$.

The output of the encoder is $S = [S_0, S_1, ..., S_{N-1}]$.

The received signal vector of the $k$th antenna is

$$Y_i = \sqrt{E_s} H(\theta) e^{j2\pi k} S_i + n_i$$

The maximum likelihood decoding algorithm is employed:

$$\hat{S} = \arg \min_s \sum_{i=0}^{N-1} \| Y_k - \sqrt{E_s} H(\theta) S_i \|^2$$

### 3 MIMO Coding Schemes for LTE

The typical applications of MIMO are spatial multiplex and spatial diversity. The multiplex system (such as BLAST) increases the transmit rate, while the diversity system could increase the physical link reliability. In all cases of MIMO system, there are given multiplex gain and diversity gain. Increasing the number of Tx antennas provides a significant performance improvement. However, the decoding complexity becomes very high for a large number of Tx antenna.

Many STC-STD algorithms have been presented to apply for a wideband system, especially for the 3G-LTE.

#### 3.1 STBC Scheme

All of the STBC schemes could be applied to MIMO-OFDM system. Assuming that the number of OFDM sub carriers is $N$, the interval of input signal is $T_s$, then the interval of data block is $N T_s$.

Suppose that two successive data vectors are $S_1$ and $S_2$, respectively, where $S_1 = [S_1(0), ..., S_1(N-1)]^T$, $S_2 = [S_2(0), ..., S_2(N-1)]^T$ and the length of the vector is $N$. Based on Alamouti’s design [5], during the first symbol transmission interval, two vectors of signals $S_1$ and $S_2$ are transmitted from antenna 1 and 2, respectively. In the second interval $-S_2^*$ and $S_1^*$ are transmitted.

The received signals at the $k$th subcarrier of $r$th antenna at the first symbol period and next period are

$$Y_{i,1}[k] = H_{i,1}[k] S_1[k] + H_{i,2}[k] S_2[k] + \eta_{i,1}[k]$$

$$Y_{i,2}[k] = -H_{i,1}[k] S_2^*[k] + H_{i,2}[k] S_1^*[k] + \eta_{i,2}[k]$$

(∀i ∈ {1, 2, ..., $M_R$}, $s$)

The receiver constructs two decision statistics based on the linear combination of the received signals

$$\tilde{S}_1[k] = \sum_{i=1}^{M_t} H_{i,1}^*[k] Y_{i,1}[k] + \sum_{i=1}^{M_t} H_{i,2}^*[k] Y_{i,2}[k]$$

$$\tilde{S}_2[k] = \sum_{i=1}^{M_t} H_{i,1}^*[k] Y_{i,2}[k] - \sum_{i=1}^{M_t} H_{i,2}^*[k] Y_{i,1}[k]$$

These are the input of the maximum likelihood decoder.

Substituting (11) into (12) and (13):

$$\tilde{S}_1[k] = \sum_{i=1}^{M_t} \sum_{q=1}^{M_t} [H_{i,q}[k]]^2 S_q[k]$$

$$+ \sum_{i=1}^{M_t} H_{i,1}^*[k] \eta_{i,1}[k] + \sum_{i=1}^{M_t} H_{i,2}^*[k] \eta_{i,2}^*[k]$$

$$\tilde{S}_2[k] = \sum_{i=1}^{M_t} \sum_{q=1}^{M_t} [H_{i,q}[k]]^2 S_q[k]$$

$$+ \sum_{i=1}^{M_t} H_{i,1}^*[k] \eta_{i,1}[k] - \sum_{i=1}^{M_t} H_{i,2}^*[k] \eta_{i,2}^*[k]$$
It can be seen that, for transmit signal pairs of $S_n[k]$, the decision statistics input is the linear combinations of $M_nM_T$ signals. When the fading of the channel between any Tx and Rx antenna pair is mutually independent, the scheme can achieve a full transmit diversity of $M_nM_T$.

The average symbol error probability (SER) can be expressed as

$$P(E) = \frac{1}{\pi} \int_0^{\pi} \prod_{i=1}^{M_T} \prod_{q=1}^{M_T} M_{\gamma_{i,q}} \left( \frac{\rho_0}{M_T^2 \sin^2(\theta)} \right) d\theta$$

Where $\rho_0 = \frac{P}{\sigma_v^2}$ is SNR, $P$ is total transmit power, $\sigma_v^2$ is noise variance, $\gamma_{i,q} = |H_{i,q}[k]|^2$ and $M_{\gamma_{i,q}} = \int_0^{\infty} p(\gamma_{i,q}) e^{\gamma_{i,q}/\rho} d\gamma_{i,q}$.

3.2 SFBC Scheme

For the STBC MIMO-OFDM the traditional STBC scheme was applied to each narrow sub-channel of a broadband system. SFBC MIMO-OFDM is also based on Alamouti’s scheme. Its coding, however, is processed in frequency-space domain.

Let $S_n = [S_n(0),\cdots,S_n(N-1)]^T$ is the information symbol, for a 2 Tx system the SFBC encoder outputs $S_{n,1}$ and $S_{n,2}$ to antenna 1 and 2 during the $n$ th symbol interval, respectively. The coding outputs are

$$S_{n,1} = [S_n[0] \cdots S_n[N-2] \cdots S_n[0]]^T$$

$$S_{n,2} = [S_n[0] \cdots S_n[N-1] \cdots S_n[N-2]]^T$$

Let $S_{ne}$ and $S_{no}$ are the vectors constructed by taking the even and odd components of $S_n$, respectively. $S_{n,1,e}$, $S_{n,1,o}$, $S_{n,2,e}$, $S_{n,2,o}$ are symbol vectors of odd and even sub-carriers of corresponding transmitter, then

$$S_{n,1,e} = S_{n,e}$$

$$S_{n,1,o} = -S_{n,o}$$

$$S_{n,2,e} = S_{n,o}$$

$$S_{n,2,o} = -S_{n,e}$$

When the guard interval exceeds the maximum time delay of channel, the received signal vector at the $i$th Rx antenna is

$$Y_{n,i} = H_{n,i,1}^* S_{n,1} + H_{n,i,2}^* S_{n,2} + Z_{n,i}$$

where $H_{n,i,1}$, $H_{n,i,2}$ are channel response diagonal matrix. Using the odd and even part expression, Eq.(21) can be expressed as

$$Y_{n,i,e} = S_{n,e} + H_{n,i,2}^* S_{n,o} + Z_{n,i,e}$$

$$Y_{n,i,o} = -H_{n,i,1}^* S_{n,o} + H_{n,i,2}^* S_{n,e} + Z_{n,i,o}$$

Thus the results of the following linear transformation can be used to do ML decision processing

$$\hat{S}_{n,e} = \sum_{i=1}^{M_T} \left( H_{n,i,1,e}^* Y_{n,i,e} + H_{n,i,2,o}^* Y_{n,i,o} \right)$$

$$\hat{S}_{n,o} = \sum_{i=1}^{M_T} \left( H_{n,i,2,e}^* Y_{n,i,e} - H_{n,i,1,o}^* Y_{n,i,o} \right)$$

3.3 SFTC Scheme

The SFTC MIMO-OFDM is derived from STTC (Space Time Trellis Coding). Its encoder is determined by the coefficients sets. The number of coefficients sets depends on the modulation scheme. Figure 3 [2] shows an encoder for QPSK, whose coefficients sets are: $\{a_p, p = 0,1,\cdots,v_1\}$ and $\{b_p, q = 0,1,\cdots,v_2\}$, where $a_p = [a_{p_1},a_{p_2},\cdots,a_{p_{M_T}}]$ and $b_q = [b_{q_1},b_{q_2},\cdots,b_{q_{M_T}}]$.

![Fig 3 structure of SFTC](image-url)
For QPSK, the data stream was split into 2 sub-streams (3 sub-streams for 8PSK), and then send to SFTC coder. The constrained length of codec is $v = v_1 + v_2$, where $v_i = \left\lfloor \frac{v + i - 1}{2} \right\rfloor$. At the time $t$, the symbol transmitted from $k$ transmitter is

$$x_i^k = (\sum_{p=0}^{v_1} l_{i-p}^k a_i^p + \sum_{q=0}^{v_2} l_{i-q}^k b_i^q) \mod 4$$  \hspace{1cm} (26)$$

where $l_{i-p}$ is the bits in the $l$th sub-data stream, at time $t-p$, the coder output $x_i = [x_1^1, x_1^2, \cdots, x_M^M]$ is mapped to the constellation symbols and the coding matrix is $G^T = [a_0^T, b_0^T, a_1^T, b_1^T, \cdots]$.

SFTC uses vector Viterbi decoding algorithm. If SFTC is applied on all sub-carriers, for large number of carriers the decoding procedure is very complex. One way to overcome this difficulty is to group the sub-carriers, and apply the SFTC on different groups. This scheme, however, will suffer performance lost.

### 3.4 Group Layered SFC Scheme

A group layered SF coding (SFC) system was proposed [3], shown in Fig 4. It has multiple identical SFC at the Transmitter. The decoding processing chain related to an individual sub-stream is referred to as a layer.

![Fig 4 structure of Group Layered SFC](image)

#### 3.5 MIMO Scheme Comparison

The two schemes derived from narrow-band STBC - STBC and SFBC are attractive. All of the STBC like schemes could be applied to MIMO 3G-LTE.

For STBC scheme the traditional STBC scheme was applied for each sub-carrier of OFDM, whereas SFBC scheme makes the coding and decoding processing in frequency and space domain. Both STBC and SFBC scheme concentrates on maximizing diversity gain. They usually provide diversity gain without coding gain.

STTC and SFTC can obtain diversity gain and coding gain at the same time. SFTC (STTC) scheme is based on TCM, which is a joint design of error control coding, modulation, transmit and receive diversity. It can simultaneously offer a substantial coding gain, spectral efficiency, and diversity improvement. However, the complexity of the SFTC (STTC) decoding (denoted by the number of trills states) is increased exponentially with transmit diversity gain $d$ and transmit rate $b$, and may not be feasible for many applications.

[6] and [7] propose a Space-Frequency-Time (SFT) scheme, which can achieve the maximum diversity gain. However, its spectral efficiency is lowered because of the coding redundancy.

#### 3.6 Channel Estimation

The PSA channel estimation is shown in Fig.5. Two significant issues for PSA approach are: (a) the design of the pilot symbol pattern at transmitter; (b) the estimation of channel state information at all subcarriers and symbols based on the receiving pilot at the receiver.

For the receiver it first obtain channel estimation at pilot symbols, then to obtain the channel state information at all the symbols by using transformation (IFFT-FFT)[10], interpolation [11], filtering [12] and so on.

**3.6.1 Pilot Pattern**

Two-dimension rectangular pilot pattern for a resource block (12 sub-carriers $\times$ 7 OFDM symbols )[16] of LTE downlink is shown in Fig.6 (taking $M_r = 2$ for instance), where $D_t$ is the time interval between two adjacent pilot symbols (for LTE resource block $D_t = 3n$ or $D_t = 4n$) , and $D_f$ is the distance between two adjacent Pilot subcarriers. For the $q$th $\text{Tx}$ (transmitter) antenna, the following $k_{q,p}$th subcarriers are selected to transmit the Pilots

$$k_{q,p} = p D_f + q - 1 \; \text{for} \; p = 0, 1, \cdots, P - 1; \; P = \left\lfloor \frac{N}{D_f} \right\rfloor$$

where $P$ is the number of training pilots for a transmit antenna and $N$ is the number of subcarrier of an OFDM symbol.
In order to recover channel state for all the subcarrier and symbols the pilot patterns should satisfy the multi-dimension Nyquist sampling theorem [12]:

$$f_{D_{\text{max}}}T_{s} \cdot D_{i} \leq 1/2 \quad \tau_{D_{\text{max}}} \Delta F \cdot D_{f} \leq 1/2$$  (27)

where $f_{D_{\text{max}}}$ is the maximal Doppler frequency spread and $\tau_{D_{\text{max}}}$ is the maximal multipath delay spread, $\Delta F$ is the subcarrier interval and $T_{s}$ is the OFDM symbol period. Usually a double oversampling will be used in a practical system.

The spectral efficiency loss for the rectangular pilot pattern is

$$\eta_{0} = \frac{M_{T}}{D_{i}D_{f}}$$  (28)

### 3.6.2 Channel Estimation at Pilot Symbols

Suppose that the MIMO-OFDM system is equipped with $M_{T}$ Tx(transmitting) antennas and $M_{R}$ Rx (receiving) antennas. The channel response between the $q$th Tx antenna and the $i$th Rx antenna is

$$h_{i,q}[n] = [h_{i,q}[n,0], h_{i,q}[n,1], \ldots, h_{i,q}[n,L-1]]^{T}$$  (29)

where $n$ is the OFDM symbol index, $i = 1, 2, \ldots, M_{R}$, $q = 1, 2, \ldots, M_{T}$ and $L$ is the FIR channel order. When the guard interval ($N_{g}$) exceeds the maximum time delay spread of the channel, the Inter-Symbol-Interference (ISI) can be neglected and the signal model in frequency domain can be expressed as

$$y_{i}[n] = \sum_{q=1}^{M_{T}} H_{i,q}[n,k]S_{q}[n,k] + v_{i}[n,k]$$  (30)

where $y_{i}[n,k]$ is the received signal at the $i$th antenna, $S_{q}[n,k]$ is the symbol transmitted by the $q$th Tx.
antenna, \( H_{i,q}[n,k] \) = \( \sum_{i=0}^{L} h_{i,q}[n,l]e^{-j2\pi kl/N} \) is the channel frequency response at the \( k \)th subcarrier of \( n \)th OFDM symbol between the \( q \)th Tx antenna and the \( i \)th Rx antenna and \( l[n,k] \) is AWGN noise with mean zero and variance \( \sigma^2 \).

Using the known Training Pilots and the corresponding received symbols, the frequency response for the \( k_q,p \)th pilot estimated by LS method is

\[
\hat{H}_{i,q}[n,k_q,p] = \frac{Y[n,k_q,p]}{S_q[n,k_q,p]}
\]

(31)

Let \( \hat{H}_{i,q} = [\hat{H}_{i,q}[n,k_0], \hat{H}_{i,q}[n,k_1], \cdots, \hat{H}_{i,q}[n,k_{N-1}]]^T \), the time domain channel response between the \( q \)th Tx and the \( i \)th Rx antenna is

\[
\hat{h}_{i,q}[n] = \left( \frac{1}{P} \right) W_q^H \hat{H}_{i,q}; \quad i = 1, 2, \cdots, M_T; \quad q = 1, 2, \cdots, M_R
\]

(32)

where \( W_q \) is a \( P \times N \) matrix whose \((k,m)\)th element is

\[
[W_q]_{k,m} = e^{-j2\pi(q-1+kM_T)(m-1)/N}
\]

(33)

\( \hat{h}_{i,q}[n] = [\hat{h}_{i,q}[n,0], \hat{h}_{i,q}[n,1], \cdots, \hat{h}_{i,q}[n,N-1]]^T \) is an \( N \times 1 \) complex vector consisting of \( N \) estimated fading coefficients. In real wireless environments, the number of fading paths is limited and thus most of the estimated coefficients in \( \hat{h}_{i,q}[n] \) might be the estimation error. The Significant Taps Catch (STC) technique [14] is employed in the scheme to pick out \( I \) paths with larger power gains \( |\hat{h}_{i,q}[n,l]| \). After STC the channel coefficients can be expressed by the vector pairs

\[
[\ell_0^{(q)}, \ell_1^{(q)}, 2, \cdots, \ell_I^{(q)}] \]

\( \hat{h}_{i,q}[n] = [\hat{h}_{i,q}[n,l_0], \hat{h}_{i,q}[n,l_1], \cdots, \hat{h}_{i,q}[n,l_I]]^T \)

(34)

where \( q = 1, 2, \cdots, M_T; i = 1, 2, \cdots, M_R \).

The STC technique reduces the estimation error and the complexity of the adaptive tracking process significantly.

### 3.6.3 Adaptive tracking for time-varying

Time domain adaptive tracking algorithm is resorted to tracking the time varying channels. Based on the STC results, the estimation of the MISO channel between the \( M_T \) Tx antennas and the \( i \)th Rx antenna can be rewritten as

\[
\hat{h}_i[n] = [\hat{h}_{i,1}[n], \hat{h}_{i,2}[n], \cdots, \hat{h}_{i,M_T}[n]]^T
\]

(35)

According to the MMSE criterion, the cost function of the estimation is

\[
J(\hat{h}_i[n]) = E[|Y[n,k_p] - \hat{Y}[n,k_p]|^2]
\]

(36)

where

\[
\hat{Y}[n,k_p] = \sum_{q=1}^{M_R} S_q[n,k_p] H_{i,q}[n,k_p] = \hat{h}_i[n] w_p[n]
\]

(37)

for \( p = 0, 1, \cdots, P-1 \) and

\[
w_p[n] = [w_{i,p}[n], w_{i,2}[n], \cdots, w_{i,M_T}[n]]^T
\]

(38)

Substitute (37) into (36), the cost function becomes

\[
J(\hat{h}_i[n]) = E[|Y[n,k_p] - \hat{h}_i^H[n] w_p[n]|^2]
\]

(39)

A LMS-Like algorithm is employed to find the optimal estimation of the channel coefficients. Let \( \hat{h}_i[n,p] \) be the estimation of optimal \( \hat{h}_i[n] \) after \( P \) times iteration, the instantaneous estimate of the gradient vector of

\[
J(\hat{h}_i[n,p])
\]

(40)

is

\[
\nabla J(\hat{h}_i[n,p])
\]

(41)

\[
= -2w_p^H[n]Y[n,k_p] + 2w_p[n]w_p^H[n]\hat{h}_i[n,p]
\]

(42)

Here \( [\cdot]^H \) donates the vector conjugate. Let

\[
e[n,p] = Y[n,k_p] - w_p^H[n]\hat{h}_i[n,p]
\]

(43)

The estimation is updated as

\[
\hat{h}_i[n,p+1] = \hat{h}_i[n,p] + \mu \nabla J(\hat{h}_i[n,p])
\]

(44)

where \( \mu \) is the step size. To guarantee the convergence property of the algorithm, \( \mu \) is selected to satisfy \( 0 < \mu < \frac{1}{M_T L} \).

Since usually channel varies continuously between successive OFDM symbols, it is reasonable to initialize the estimation in the current OFDM symbol by the estimation results in the previous OFDM symbol, i.e.

\[
\hat{h}_i[n,0] = \hat{h}_i[n-1]
\]

(45)
For each of the $M_r$ Rx antennas, after $P$ iterations the final estimation for $n$th OFDM symbol is

$$h_r[n] = h_r[n, P]$$

(46)

The frequency response $H_{rx}[n,k]$ is obtained by using FFT.

For LS algorithm the cost function of the estimation is

$$J(\hat{h}[n]) = \sum_{p=0}^{P-1} |Y[n,k_p] - \hat{h}^T[n]w_p[n]|^2$$

(47)

where $Y[n,k_p]$ and $w_p[n]$ are obtained by the reference pilots and STC. Based on the same assumption as the above LMS algorithm, the optimal LS estimation is

$$\hat{h}[n] = (W^H[n]W[n])^{-1}W^H[n]Y_p[n]$$

(48)

where $W[n]$ is defined as

$$W[n] = [w_1[n], w_2[n], \ldots, w_{P-1}[n]]^T$$

(49)

and $Y_p[n] = [Y[n,k_1], Y[n,k_2], \ldots, Y[n,k_{P-1}]^T$.

A modified cost function with forgetting factor $\lambda (0 < \lambda \leq 1)$ is

$$J(\hat{h}[n, p]) = \sum_{u=0}^{P-1} \lambda^{P-u} |Y[n,k_u] - \hat{h}^T[n]w_u[n]|^2$$

(50)

RLS (recursive LS) algorithm derived from Eq.(50) is listed in Table 1.

4 Simulation results

To demonstrate the performance of the MIMO scheme discussed, computer simulation has been carried out.

Firstly, in order to compare performance of these MIMO schemes, we assume that the receiver could obtain the exact CSI and recover the carrier frequency correctly.

Assuming the channel is macro Urban scenario [4], carrier frequency of 2.15GHz, the height of base station is 10m, the mobile height is 1.5m; the bandwidth of 5MHz; The channel is composed of $6 \times 20$ sub-paths, the transmit power of a single antenna shall be the same as the each transmit power of a multiple antenna case. Considering the QPSK modulation and the down-link channel, $N = 1024$, $N_s = 40$. The receiver signal-to-noise-ratio (SNR) is defined as

$$\text{SNR} = \frac{\left(\left\|\sum_{k=1}^{N_s} H_{rx}[n,k] \right\|^2 \right)}{\sigma^2}.$$

Assuming that, the guard interval exceeds the maximum time delay of the channel, so the IBI can be neglected. The transmitting power for all the simulations is identical and equally distributed to each antenna.

Figure 7 compares the performance of SFBC and 16-state SFTC under same channel and antenna structure. The figure shows that the performance of SFTC system is superior to the SFBC system. The SFTC system brings a 2.3dB improvement at a BER of $10^{-4}$ than SFBC system. It is because that the
carefully designed SFTC can offer both diversity gain and coding gain, with the cost of the increasing of the decoding complexity.

Figure 8 shows the impact of fast fading channel on STBC-OFDM. It assumed that the channel keeps constant over 2 successive STBC-OFDM symbols. The performance of a system with the velocity of 30km/h is worse than the system of constant channel by 1~2dB loss. This is because that the fast fading of channel destroys the orthogonal of Alamouti scheme.

The fast fading could offer an extra diversity gain: Doppler diversity. To obtain the Doppler gain, much work had to be done with the channel estimating and decoding processing.

Secondly, to demonstrate the performance of the PSA channel estimation discussed, a space frequency trellis coded system with QPSK constellation, 16 states, 2 Tx antennas and 2 Rx antennas is used. The channel is generated based on the ITU-Vehicular Channel B [15] Raleigh fading channel model. A 5MHz channel is divided into \( N = 1024 \) sub-channels \( N_g = 40 \) and
\( f_c = 2150 \text{ MHz} \). It is assumed that there are \( D_t = 40 \) OFDM symbols in each frame.

Fig.13 BER with different vehicular speed (RLS)

Fig.12 and Fig.13 shows the Bit Error Rate (BER) of the system with the LMS and RLS channel tracking approach. In each information OFDM symbol, 64 reference pilots are used for the LMS-Like tracking algorithm with \( \mu = 0.02 \), \( L = 6 \) and the RLS tracking algorithm with \( \lambda = 0.99 \) and \( L = 6 \). The spectral efficiency loss is 8.6%. There is about 1dB SNR gap for the systems using the ideal and estimated channel coefficients with different Doppler frequency (60Hz, 120Hz, and 180Hz). For estimating one parameter of \( \hat{H}_w[n,k] \), \( (2P\bar{L} + N/2\log_2[N])/N \) complex multiplication per parameter are required, which is 5.744/parameter. Among them, only 0.744 complex multiplication/parameter is consumed by the adaptive algorithm and the remaining are for the basic processing required by all the FFT assisted channel estimation schemes.

Fig.14 BER versus SNR with different \( \bar{L} \) (LMS 30km/h)

Fig.14 illustrates the BER performance with different \( \bar{L} \) when LMS algorithm is employed and the vehicular speed is 30km/h. The real channel used in the simulation has 3 paths. \( \bar{L} \) is selected to be 2, 3, 6 and 9. It indicates that the path number of STC is different from the real will cause performance degradation. And STC without enough effective paths (\( \bar{L} = 2 \)) is worse that STC with overfull path (\( \bar{L} = 9 \)).

In Fig.15 shows a comparison of LMS and RLS channel tracking and PSA-interpolation. \( \bar{L} \) is set to 6. For the PSA-Interpolation, \( \bar{L} = 4 \) and \( D_t = 5 \), and 1st order interpolation is used. Its spectral efficiency loss is 10%. For LMS (\( \mu = 0.02 \)) and RLS (\( \lambda = 0.99 \)), \( D_t = 40 \) and \( P = 64 \). The spectral losses are 8.6% for both the cases. It indicates that the three schemes have almost the same performance in BER. However, the two adaptive schemes have higher spectral efficiency and are more attractive to systems with large transmitter arrays.

5 Conclusion

In this paper, we discussed the combination of MIMO schemes for the downlink channel in 3G Long-Term Evolution (3G-LTE). The coding and decoding schemes in a time-variable multipath environment are discussed. In particular, the STBC/SFBC, SFTC/STTC and Group layered SFC coding-decoding schemes, were taken into account. Their performance including the computation complexity, frequency efficiency, BER and the effects of channel estimation, are compared. Furthermore, computer simulation results for these
schemes. We believe that results will provide beneficial information to design MIMO scheme for the 3G-LTE downlink.
